(Received 23 March 1990; accepted 16 January 1991)

Summary — Nodulated soybeans, *Glycine max* (L Merr), were grown under 6 photon flux densities (PFD) from 0.35–1.03 mmol photons $m^{-2}\cdot s^{-1}$, in order to determine the optimal light intensity for symbiotic nitrogen fixation in controlled environment. The nitrogenase activity (C_2H_2 reduction) was highest at 0.68 mmol photons $m^{-2}\cdot s^{-1}$ which also corresponded to the highest growth of plants and the biggest mass of nodules. The specific acetylene reducing activity was not affected by PFD, except at 1.03 mmol photons $m^{-2}\cdot s^{-1}$, where it was much lower. Decreasing the PFD had no effect on nitrogenase activity during the following 24 h. By contrast, an increase in PFD rapidly induced a significant decline of nitrogenase activity. At a similar PFD, the periodic light fluctuation was less beneficial than steady illumination for growth and nitrogen fixation. It is concluded that plant photosynthesis determines nodule mass which in turn determines the rate of nitrogen fixation. Nodule nitrogenase activity is not directly regulated by concurrent photosynthesis however, probably because of available photosynthate reserves and other regulatory mechanisms. Excess of light inhibits nitrogenase activity.

nitrogenase / nodules / photosynthesis / *Rhizobium* / *Glycine max* = soybean

Résumé — Influence de la densité et de la fluctuation du flux de photons sur la fixation symbiotique de l'azote par *Glycine max*–*Bradyrhizobium japonicum*. Dans l'objectif de déterminer l'intensité lumineuse optimale pour la fixation symbiotique de l'azote en milieu contrôlé, des sojas nodulés ont été cultivés sous 6 densités de flux de photons (DFP) comprises entre 0,35 et 1,03 mmol(photons) $\cdot m^{-2}\cdot s^{-1}$ (fig 1). L'activité nitrogénase (réduction de l'acétylène) est la plus élevée à 0,68 mmol(photons) $\cdot m^{-2}\cdot s^{-1}$ (fig 2), densité de flux de photons qui correspond également aux croissances de plante et aux masses modulaires les plus élevées (fig 1). L'activité spécifique de réduction de l'acétylène par les nodosités n'est pas affectée par la DFP, excepté à 1,03 mmol(photons) $\cdot m^{-2}\cdot s^{-1}$ pour laquelle elle est plus faible (fig 2). La diminution de la DFP n'a pas d'effet sur l'activité nitrogénase pendant au moins 24 h (fig 3). Au contraire une augmentation de la DFP provoque rapidement une diminution significative de l'activité nitrogénase (fig 3). Pour une même DFP, un éclairage périodique comparé à un éclairage stable induit une croissance et une activité nitrogénase plus faibles (fig 2). La photosynthèse détermine donc la masse nodulaire qui en retour détermine la vitesse de fixation de l'azote. Cependant, l'activité nitrogénase nodulaire n'est pas directement régulée par la photosynthèse simultanée, probablement du fait de l'existence de réserves de photosynthats et d'autres mécanismes de régulation. Un excès de lumière inhibe spécifiquement la fixation d'azote.

nitrogénase / nodule / photosynthèse / *Rhizobium* / *Glycine max* = soja

INTRODUCTION

Nitrogen fixation by soybean–*Bradyrhizobium japonicum* symbiosis depends upon photosynthesis that provides substrates for nodule maintenance, nitrogenase activity and incorporation of reduced nitrogen into amino acids (Salsac *et al*, 1984). The amount of nitrogen fixed during the growth cycle is generally limited by the photosynthetic activity of the macrosymbiont since it increases in plants grown in enriched CO₂ atmosphere (Wilson *et al*, 1933; Hardy and Havelka, 1976) and varies with the intensity of shoot illumination (Bethlenfalway and Phillips, 1977; Antoniw and Sprent, 1978; Silsbury, 1981). The major effect of long-term manipulation of photosynthesis appears to be on the mass of nodules. Its effect on nodule nitrogenase activity, as measured by acetylene reducing activity ARA (Hardy *et al*, 1968) was less consistent: in the presence of an enriched CO₂ atmosphere, the specific, *ie* per nodule, acetylene reducing activity (sARA) was higher than that in air for clover (Masterson and Sherwood, 1978), higher or similar for soybean (Hardy and Havelka, 1976; Finn and Brun, 1982; Williams *et al*, 1982), and similar or lower for pea (Masterson and Sherwood, 1978; Phillips *et al*, 1976). Thus Sheikholeslam *et al* (1980) suggested that the modification of photosynthesis affects nitrogen fixation by altering plant development rather than by changing the amount of energy translocated to the nodules.

In this study nodulated soybean plants were grown in a growth chamber under various light intensities to determine the critical photon flux density (PFD) for nitrogen fixation by this symbiosis in a controlled environment. Both steady and periodically fluctuating PFD were imposed. In order to monitor the short-term effect of photon flux density on the sARA, plants grown under a steady illumination were submitted to higher or lower steady photon flux densities over a 24-h period.

MATERIALS AND METHODS

Biological material and growth conditions

Soybean (*Glycine max* cv Hodgson) seeds were surface-sterilized, inoculated with *Bradyrhizobium japonicum* strain PJ 17 and grown in a liquid aerated nutri-

ent medium as described previously (Kalia and Drevon, 1985). The conditions of cultivation in the growth chamber were 16/8 h light/dark cycles at 25/18 °C, ≈ 60% relative humidity. The serum bottle containing the nodulated root were wrapped in aluminium foil in order to prevent any direct effect of light on nodules.

Under steady illumination, plants were placed at increasing distances from a fixed beam carrying 13 1 000-W mercury vapor lamps. In the case of fluctuating illumination, plants were placed in a similar growth chamber and the only difference was that the beam carrying the light sources was displayed regularly at a speed of 5 m·min⁻¹ (this device has been patented by Rhône-Poulenc Agrochimie Company and is manufactured by Retma Company, Lovie/Rhône, Givors, France). Photon flux densities (PFD; 1 mmol photons m⁻²·s⁻¹ equals ≈ 70 000 lux) were measured with a Li-Cor at the level of the second trifoliolate leaf; values are shown in figures and tables.

Plants received 1 mM urea during the first 28 d of cultivation, otherwise plants under high intensities might have suffered a transient detrimental nitrogen deficiency (Williams and Phillips, 1980).

Nodule nitrogenase activity measurement

In this work, the nitrogenase catalyzed ARA was assayed *in situ* in closed vessels according to previously described experimental conditions (Kalia and Drevon, 1985). Gas samples of inner incubation atmosphere were taken 20 and 40 min after the acetylene injection. Ethylene and acetylene concentration were monitored on a Girdel 30 gas chromatograph (porapak T column, 1.2 m long, 3.2 mm diameter; N₂ carrier gas 30 ml·min⁻¹; oven temperature 80 °C).

The ARA was measured on 42–45-d-old plants when they were still at a similar developmental stage, *ie* 5 leaves, and had a maximum sARA according to previous observations by Kalia and Drevon (1985) on hydroponically grown soybeans. The temperature in the root environment was 28 °C.

Relevant ARA data could be obtained for these hydroponically-grown soybeans without an open flow system; indeed, with a flowing gas stream, no significant decline in nitrogenase activity (C₂H₂ reduction) of hydroponically-grown soybean was induced by acetylene (Weisz and Sinclair, 1987; Drevon *et al*, 1988). This observation contrasts with those obtained by a similar method with plants grown on perlite (Minchin *et al*, 1986).

Dry weight of plants and nodules were measured after 48 h at 80 °C

Statistical analyses were performed either by 2-way analysis of variance for the comparison of data at a given light intensity, or by regression and covariance

analysis for the significance of light effect on plant and nodule parameters in the intervals of 0.35 to 0.68 mmol photons $m^{-2}\cdot s^{-1}$ and of 0.68–1.03 mmol photons $m^{-2}\cdot s^{-1}$.

RESULTS

Long-term response to photon flux density

In the absence of PFD fluctuation, the maximum growth of soybean was under 0.68 mmol photons $m^{-2}\cdot s^{-1}$ (fig 1). The highest mass of nodules was also observed on plants grown in presence of this density of the photon flux. Indeed nodule mass increased from 0.14 g DW pl^{-1} at 0.35 mmol photons $m^{-2}\cdot s^{-1}$ to 0.59 g DW pl^{-1} at 0.68 mmol photons $m^{-2}\cdot s^{-1}$ (fig 1). This increase of nodule mass was mostly due to a higher individual nodule mass (table I). It was highly correlated with plant growth ($r = 0.99$) which confirms the above-mentioned reports on the long-term effect of altered photosynthesis on nodulation.

The highest ARA was observed on plants grown under 0.68 mmol photons $m^{-2}\cdot s^{-1}$ (fig 2). From a regression analysis of the data in figure 1 and in replicated similar experiments (data not shown), it can be extrapolated that the optimal

Influence of steady photon flux density on soybean growth of shoots (\blacktriangle), roots (\blacktriangledown) and nodules (\bullet) and fluctuating photon flux density on soybean growth of shoots (Δ), roots (\triangledown) and nodules (\circ). Data are means of 5 43-d-old plants for each growth illumination.

Table I. Influence of steady photon flux density on nodulation of soybean. Data are means \pm standard deviation of 5 replicates. Mean individual nodule mass was obtained by dividing total nodule mass per plant shown in figure 1, by number of nodules per plant in this table. Plants were 43-d old.

mmol Photons $m^{-2}\cdot s^{-1}$	No nod. pl^{-1}	mg (DW) nod^{-1}
0.35	207 \pm 67	0.68
0.43	233 \pm 83	1.12
0.52	231 \pm 84	1.29
0.68	334 \pm 98	1.77
0.85	277 \pm 84	1.85
1.03	77 \pm 22	3.68

PFD for soybean symbiotic nitrogenase activity was very close to 0.7 mmol photons $m^{-2}\cdot s^{-1}$. Above the optimal PFD, the ARA declined drastically, thus at 1.03 mmol photons $m^{-2}\cdot s^{-1}$ it was 4% of the ARA at 0.68 mmol photons $m^{-2}\cdot s^{-1}$ (fig 2).

By contrast, the sARA (ARA per g nodule) was diversely affected by PFD and varied greatly from one experiment to another. On some days it was higher at suboptimal PFD than at optimal PFD, while on other days the effect was reverse. Consequently the mean data for each PFD in various experiments were not significantly different except at 1.03 mmol photons $m^{-2}\cdot s^{-1}$, where it was always very low (fig 2). This detrimental effect of high PFD was greater for nitrogenase activity (which was only 8% of the opti-

Fig 2. Influence of steady photon flux density on soybean root nodule nitrogenase activity (C_2H_4 reduction) per plant (\bullet) and per g (DW) nodules (\blacksquare), and fluctuating photon flux density on soybean root nodule nitrogenase activity (C_2H_4 reduction) per plant (\circ) and per g DW (\square). Data are means and SD of 5 42-d-old plants for each growth illumination.

mal ARA), than for nodule mass or plant growth which were respectively 48% and 44% of the optimal values (fig 1).

Short-term effects of photon flux density

In studying the short-term effect of various illuminations, 20 plants grown under 0.52 mmol photons $m^{-2}\cdot s^{-1}$ were distributed randomly into 4 groups of 5 plants each. One group was maintained under this illumination; 3 other groups were transferred under 0.20, 0.40 and 0.80 mmol photons $m^{-2}\cdot s^{-1}$. Temperature was maintained at 25 °C during a complete diurnal cycle and during the previous 24 h to avoid any nodule perturbation due to temperature change (Schweitzer and Harper, 1980).

Diurnal cycle

The ARA assays performed at different times over a 24-h period revealed some fluctuation during the diurnal cycle (fig 3). The optimal activity was observed between 6–12 h after the be-

ginning of the light period. It decreased before the beginning of the dark period during which the activity remained at a constant level. The ratio of maximum/minimum rates of nitrogenase activity during the diurnal cycle varied between 1.35–1.45 under 0.20, 0.40 and 0.52 mmol photons $m^{-2}\cdot s^{-1}$.

Change of light intensities

Removing plants from 0.52 mmol photons $m^{-2}\cdot s^{-1}$ to 0.40 and 0.20 mmol photons $m^{-2}\cdot s^{-1}$ had no short-term effect on nodule activity (fig 3). Therefore, nodule nitrogenase activity was not directly dependent on photosynthesis, probably because of available substrate reserves.

Removing plants from 0.52–0.80 mmol photons $m^{-2}\cdot s^{-1}$ induced a significant decrease in nitrogenase activity (fig 3). The decline was detected as soon as 150 min after the plants were exposed to the new environment. Thus between 9 and 11.30 am, the ARA increase was only 16% under 0.80 mmol photons $m^{-2}\cdot s^{-1}$ compared with \approx 40% in control. After 25 h, the nitrogenase activity under 0.80 mmol photons $m^{-2}\cdot s^{-1}$ was only 64% of its initial value, although in other treatments it was at least similar. The lowest ARA was observed at the end of the light period, when nodule activity of plants under 0.80 mmol photons $m^{-2}\cdot s^{-1}$ was 50% lower than that of plants maintained under 0.52 mmol photons $m^{-2}\cdot s^{-1}$. A similar negative effect of increase of PFD on ARA was observed after exposure to 0.85 mmol photons $m^{-2}\cdot s^{-1}$ of soybeans grown at 0.68 (data not shown) which was close to optimal PFD growth of soybean with N_2 .

Influence of light fluctuation

At 0.35 and 0.43 mmol photons $m^{-2}\cdot s^{-1}$, ARA of plants under fluctuating PFD was lower. However, sARA at midday (fig 2) and its variation during the diurnal cycle (data not shown) were not affected by light fluctuation. The major effect of PFD fluctuation was on nodule mass which was 40% lower under fluctuating PFD than under constant similar PFD (fig 1). This might be a consequence of the lower growth of shoots under fluctuating PFD (fig 1); thus g(DW) shoot pl^{-1} was respectively 40 and 53% lower than that under steady PFD, although root growth was not apparently affected by light fluctuation. At 0.52 mmol photons $m^{-2}\cdot s^{-1}$, the differences in ARA

Fig 3. Changes in nitrogenase activity (C_2H_2 reduction) following the transfer of nodulated soybeans from 0.52 mmol photons $m^{-2}\cdot s^{-1}$ to higher and lower photon flux densities. Data are means \pm SD of 5 replicates. The ARA was repeatedly measured on similar plants. Plants were 45-d old. The black line in the horizontal axis represents the dark period.

and root and nodule masses between the 2 treatments were not significant. Higher fluctuating PFD could not be monitored in our climatic cell because of the impossibility to fix more lamps on the beam.

CONCLUSIONS

The optimal light intensity for nitrogenase activity and growth of soybeans in climatic cells was 0.7 mmol photons $m^{-2}\cdot s^{-1}$, which confirms previous observations on soybean (Williams and Phillips, 1980; Williams *et al.*, 1982; Walsh *et al.*, 1987) and pea (Bethlenfalway and Phillips, 1977). Consequently this level of light intensity would be required to study symbiotic N_2 fixation in the absence of photosynthesis limitation under artificial conditions.

For suboptimal illuminations, lower levels of nitrogenase activity were due to lower masses of nodules which suggests that nitrogen fixation was regulated by plant photosynthesis through the mass of nitrogen fixing tissue. But the specific activity of the tissue, *ie* the rate of nitrogenase activity per g nodule was independent of total plant photosynthesis (fig 2): therefore it would not be regulated by the concurrent shoot reduction of CO_2 . However, it should be pointed out that these results could possibly differ if nitrogenase inhibition by C_2H_2 (Minchin *et al.*, 1986) which was not observed at the optimal illumination (Drevon *et al.*, 1988), depended on light intensity.

ARA varied during the diurnal cycle (fig 3), which contrasts with previous observations of an absence of change in nodule activity during day-night cycle at constant temperature (Hardy *et al.*, 1968; Fishbeck *et al.*, 1973; Hart, 1976; Schweitzer and Harper, 1980; Williams *et al.*, 1982; Walsh *et al.*, 1987) but agrees with the work of Mederski and Streeter (1977). Since the decrease in nitrogenase activity preceded the dark period (fig 3), the diurnal variation of ARA did not relate directly to the shoot illumination. The maintenance of a high level of nodule activity during the dark period and during at least the 24 h following the transfer of plants to lower PFD (fig 3), which agrees with the observations of Williams *et al.* (1982), is consistent with our above conclusion and with the suggestion of Schweitzer and Harper (1980) that a reserve pool of carbohydrate could be mobilized to support nodule activity in the absence of concurrent photosynthesis. However, our results with soybean differ from those

obtained by Walsh *et al.* (1987) according to which the ARA started to decline after 20 h exposure to darkness and that of Ryle (1988) who observed that exposing white clover to darkness affected nitrogenase activity within 30–60 min.

Putative regulators of nodule nitrogenase activity and the consequent flux of energy to these organs could be the plant nitrogen demand (Mederski and Streeter, 1977; Schweitzer and Harper, 1980; Silsbury, 1981) and the oxygen supply to the bacteroids (Bergersen, 1981; Sheehy *et al.*, 1985; Drevon *et al.*, 1987), although the mechanisms involved are still unknown.

Our observation of a decline in ARA after exposing plants to PFD higher than that applied during growth confirms the results of Williams and Phillips (1980) on soybeans transferred from 0.70 to 1.50 mmol photons $m^{-2}\cdot s^{-1}$, although our treatment was less stringent. This phenomenon may be specific to soybean since it was not detected on peas transferred from 0.50 to 0.80 mmol photons $m^{-2}\cdot s^{-1}$ (Sheikholeslam *et al.*, 1980) or french beans transferred from 0.04 to 0.11 mmol photons $m^{-2}\cdot s^{-1}$ (Antoniw and Sprent, 1978). Its mechanism is not known; it differs with the early limitation of young plant nodulation by excess light (Fred *et al.*, 1938; Orcutt and Fred, 1935) which has recently been attributed to N limitation of legumes depending exclusively on N_2 fixation (Williams and Phillips, 1980). The limitation of plant nitrogen fixation and growth at supra-optimal PFD might be a consequence of N deficiency caused by this inhibition of nitrogenase activity by high PFD. This interpretation is consistent with the observation of very low specific nitrogenase activity of plants grown under 1.03 mmol photons $m^{-2}\cdot s^{-1}$.

This phenomenon of N deficiency due to inhibition of N_2 fixation by light intensities in the range of 1 mmol photons $m^{-2}\cdot s^{-1}$ is generally not observed in field-grown plants although natural illumination would be as high as 1 mmol photons $m^{-2}\cdot s^{-1}$ during a sunny day. The reason for this apparent discrepancy with our results in an artificial environment may be that, under field conditions, plants receive complementary N from soil nitrification, and are grown in a more competitive density than in our experiments. An alternative explanation is that the observed inhibition under mercury vapor lamps may be caused by the spectrum composition of this light which differs from that of natural light. These hypotheses will be tested in further experiments.

The PFD fluctuation had a negative effect on growth and nitrogen fixation at least at light intensities < 0.5 mmol photons $m^{-2}\cdot s^{-1}$. This may be due to a photoinhibitory effect of the temporarily high PFD on chloroplastic pigment concentration and chlorophyll fluorescence (Gaudillère *et al*, 1987).

ACKNOWLEDGMENTS

The authors thank Dr Evans for supplying the strain PJ 17 and Dr Vidal for supplying the seeds that were used in this experiment. This work was supported by grant 1016 from EEC DG 6.
